Abstract

Manifold regularization (MR) provides a powerful framework for semi-supervised classification (SSC) using both the labeled and unlabeled data. It first constructs a single Laplacian graph over the whole dataset for representing the manifold structure, and then enforces the smoothness constraint over such graph by a Laplacian regularizer in learning. However, the smoothness over such a single Laplacian graph may take the risk of ignoring the discrimination among boundary instances, which are very likely from different classes though highly close to each other on the manifold. To compensate for such deficiency, researches have already been devoted by taking into account the discrimination together with the smoothness in learning. However, those works are only confined to the discrimination of the labeled instances, thus rather limited in boosting the semi-supervised learning. To mitigate such an unfavorable situation, we attempt to discover the possible discrimination in the available instances first by performing some unsupervised clustering over the whole dataset, and then incorporate it into MR to develop a novel discrimination-aware manifold regularization (DAMR) framework. In DAMR, instances with high similarity on the manifold will be restricted to share the same class label if belonging to the same cluster, or to have different class labels, otherwise. Our empirical results show the competitiveness of DAMR compared to MR and its variants likewise incorporating the discrimination in learning.

1. Introduction

In many real applications, the unlabeled data can be easily and cheaply collected, while the acquisition of labeled data is usually quite expensive and time-consuming, especially involving manual effort. For instance, in web page recommendation, huge amounts of web pages are available, but few users are willing to spend time marking which web pages they are interested in. In spam email detection, a large number of emails can be automatically collected, yet few of them have been labeled spam or not by users. Consequently, semi-supervised learning, which exploits a large amount of unlabeled data jointly with the limited labeled data for learning, has attracted intensive attention during the past decades. In this paper, we focus on semi-supervised classification, and so far, lots of semi-supervised classification methods have been developed [1–4].

Generally, semi-supervised classification methods attempt to exploit the intrinsic data distribution information disclosed by the unlabeled data in learning, and the information is usually considered to be helpful for learning. To exploit the unlabeled data, some assumption should be adopted for learning. Two common assumptions in semi-supervised classification are the cluster assumption and the manifold assumption [3–5]. The former assumes that similar instances are likely to share the same class label, thus guides the classification boundary passing through the low density region between clusters. The latter assumes that the data are resided on some low dimensional manifold represented by a Laplacian graph, and similar instances should share similar classification outputs according to the graph. Almost all off-the-shelf semi-supervised classification methods adopt one or both of those assumptions explicitly or implicitly [1,4]. For instance, the large margin semi-supervised classification methods adapt one or both of those assumptions explicitly or implicitly [1,4]. For instance, the large margin semi-supervised classification methods, such as transductive Support Vector Machine (TSVM) [6], semi-supervised SVM (3SVM) [7] and their variants [8,9], adopt the cluster assumption. The graph-based semi-supervised classification methods, such as label propagation [10,11], graph cuts [12] and manifold regularization (MR) [13], adopt the manifold assumption. Furthermore, there are also methods combining both assumptions for better performances, such as RegBoost [14] and SemiBoost [15], etc.

In this paper, we concentrate on the MR framework [13], which provides an effective way for semi-supervised classification [16], and has been applied in diverse applications such as image...
retrieval [17] and web spam identification [18], etc. At the same time, the manifold learning concept has also successfully applied in many other learning tasks including clustering [19], dimensionality reduction [20], and non-negative matrix factorization [21,22], etc.

MR for semi-supervised classification represents the manifold structure for the whole dataset by a single Laplacian graph, which is different from MR for supervised classification constructing the respective Laplacian graphs for individual classes, and then imposes the smoothness constraint over such a representation by a Laplacian regularizer in learning. However, the smoothness constraint imposed over a single Laplacian graph may take the risk of ignoring the discrimination among the boundary instances, which are very likely to belong to different classes though close over the manifold, consequently, MR may misclassify the boundary instances between clusters [16].

In fact, many researches have already been devoted to compensating for this deficiency by utilizing the dissimilarity or discrimination in the learning of MR. In [23], Andrew et al. considered both the label similarity and dissimilarity in learning, and developed a new dissimilarity encoded MR framework based on mixed graph. However, the dissimilarity should be given beforehand. In [24], Wang and Zhang constructed an unsupervised discriminative kernel based on discriminant analysis, and then used it to derive specific algorithms, including semi-supervised discriminative regularisation (SSDR) and semi-parametric discriminative semi-supervised classification (SDS). However, the derived methods do not fall into the methodology of manifold regularization. Recently in [16], Wu et al. incorporated linear discriminant analysis (LDA) and MR into a coherent framework and developed a semi-supervised discriminative regularisation (SSDR) and semi-parametric discriminative semi-supervised classification (SDS). However, the derived methods do not fall into the methodology of manifold regularization. Recently in [16], Wu et al. incorporated linear discriminant analysis (LDA) and MR into a coherent framework and developed a semi-supervised discriminative regularisation (SSDR). Specifically, the intra-class and inter-class graphs are constructed first in SSDR based on the labeled data, and then the corresponding intra-class compactness and inter-class separation are optimized simultaneously in the learning of MR. However, SSDR in [16] only utilize the discrimination of the labeled data, while the label information is usually rather limited in semi-supervised learning, consequently, its improvement over MR is not so distinct in the experiments.

In this paper, we attempt to incorporate the discrimination of both the labeled and unlabeled data into MR so as to develop a discrimination-aware MR framework for semi-supervised classification. In fact, due to the lack of label information in semi-supervised learning and thus the difficulty for formulating the discrimination of the whole data, SSDR in [16] only uses the discrimination of the labeled data, while the label instances are usually scarce in semi-supervised classification. For discovering the discrimination of all given data, we adopt the strategy of a pre-performed unsupervised clustering method as an example. Specifically, by performing some unsupervised clustering method such as FCM beforehand, we can get the within/between-cluster information of all the instances, which is much analog to the mutual/cannot-link information in semi-supervised clustering. Then we incorporate such information into MR such that for instances with high similarity over the manifold structure, they are restricted to share the same class label if belonging to the same cluster, or to have different class labels, otherwise. In this way, DAMR actually utilizes both the cluster and manifold assumptions in learning. It has been demonstrated by previous work that methods working on multiple data distribution assumptions can achieve better classification than those working on a single one [14,15], thus DAMR is able to be expected to perform better than MR.

The rest of this paper is organized as follows. Section 2 introduces the related works, Section 3 presents the proposed discrimination-aware manifold regularization framework, Section 4 presents a specific algorithm DA_LapRLSC through adopting the square loss function, Section 5 gives the empirical results, and some conclusions are drawn in Section 6.

2. Related works

2.1. Manifold regularization

Manifold assumption is one of the most commonly-used data distribution assumptions in semi-supervised learning [2,4]. Generally, the manifold structure is captured by an undirected graph according to some similarity measure, in which the vertices represent the instances and the edge-weights represent the similarities between instance pairs, and the manifold assumption assumes that similar instances over the manifold structure should share similar classification outputs. Lots of semi-supervised classification methods have been proposed based on the manifold assumption, mainly including the graph-based methods such as label propagation, graph cuts and manifold regularization, etc. Most graph-based methods, including label propagation and graph cuts, aim to learn only the class labels for the available unlabeled instances, thus learn in the transductive learning style [4]. However, many real applications actually need inductive methods for predicting unseen instances [15], and manifold regularization (MR) is exactly an inductive learning framework for semi-supervised classification based on the manifold assumption, which has been applied in diverse applications during the recent years.

Given labeled data \(Y = \{y_i\}_{i=1}^n\), and unlabeled data \(X = \{x_i\}_{i=1}^m\), where each \(x_i \in \mathbb{R}^p\) and \(u = n - l\). \(G = \{W_{ij}\}_{ij=1}^n\) is a Laplacian graph over the whole dataset, where each weight \(W_{ij}\) represents the similarity between instances \(x_i\) and \(x_j\). The Laplacian graph can be defined by many strategies such as the 0–1 weighting, i.e., \(W_{ij} = 1\) if and only if \(x_i\) and \(x_j\) are connected by an edge over the graph, the heat kernel weighting with \(W_{ij} = e^{-||x_i - x_j||^2/2\sigma^2}\) if \(x_i\) and \(x_j\) are connected, or the dot-product weighting with \(W_{ij} = x_i^T x_j\) if \(x_i\) and \(x_j\) are connected.

Then with a decision function \(f(x)\), the framework of MR can be formulated as

\[
\min \frac{1}{l} \sum_{i=1}^{l} \mathcal{V}(x_i, y_i, f) + \gamma A||f||_2^2 + \frac{\mu}{2(1+u)} \sum_{i,j=1}^{l+u} W_{ij}(f(x_i) - f(x_j))^2 \tag{1}
\]

where \(\mathcal{V}(x_i, y_i, f)\) is some loss function, such as the hinge loss max \([0, 1 - y_i f(x_i)]\) for support vector machine (SVM) or the square loss \((y_i - f(x_i))^2\) for regularized least square classifier (RLSC), in this way, the MR framework naturally embodies the specific algorithms LapSVM and LapRLSC [13]. \(||f||_2^2\) is a regularization term for smoothness in the Reproducing Kernel Hilbert Space (RKHS). The third term guarantees the prediction smoothness over the graph, which can be further written as

\[
\frac{1}{u} \sum_{i,j=1}^{l+u} W_{ij}(f(x_i) - f(x_j))^2 = \mathbf{f}^T L \mathbf{f} \tag{2}
\]

where \(\mathbf{f} = [f(x_1), ..., f(x_{l+u})]^T\), and \(L\) is the graph Laplacian given by \(L = D - W\), \(W\) is the weight matrix of graph \(G\) and \(D\) is a diagonal matrix with the diagonal component given by \(D_{ii} = \sum_j W_{ij}\). According to the Representer theorem [13], the minimizer of problem (1) has the form

\[
f^*(x) = \sum_{i=1}^{l+u} \alpha_i K(x_i, x) \tag{3}
\]

where \(K: \mathbb{R}^p \times \mathbb{R}^p \rightarrow \mathbb{R}\) is a Mercer kernel (the bias of the decision function can be omitted by augmenting each instance with an 1-valued element).

It is clear that in MR, if instances \(x_i\) and \(x_j\) are similar in terms of \(W_{ij}\), then it is restricted that their class labels are similar as well. Such a smoothness restriction is also imposed on the boundary instance pairs, however, instance pairs in the boundary area are very
likely to belong to different classes. Thus in this paper, we attempt to utilize the discrimination among instances together with the smoothness over the manifold.

2.2. Semi-supervised discriminative regularization (SSDR) [16]

The performance of LDA usually deteriorates when the label information is insufficient, and at the same time, MR tends to misclassify instances near the boundary between clusters during classification [16]. With those in mind, Wu et al. [16] incorporated LDA and MR into a coherent framework for semi-supervised classification, and proposed a novel semi-supervised discriminative regularization (SSDR) method. SSDR exploits both the discrimination (label information of the labeled data) and the data distribution for learning. Specifically, besides the graph $G$ over the $(l+u)$ instances to model the intrinsic geometrical structure of data manifold, a intra-class graph $G_w$ (with weight matrix $W_w$) and a inter-class graph $G_b$ (with weight matrix $W_b$) are also constructed respectively by

$$ W_{w,ij} = \begin{cases} \frac{1}{l} & \text{if both } x_i \text{ and } x_j \text{ are labeled and } y_i = y_j \\ 0 & \text{otherwise} \end{cases} $$

(4)

$$ W_{b,ij} = \begin{cases} \frac{1}{l} & \text{if both } x_i \text{ and } x_j \text{ are labeled and } y_i \neq y_j \\ 0 & \text{otherwise} \end{cases} $$

(5)

Then the optimization problem of SSDR is formulated as

$$ \min_{f} \frac{1}{2} \sum_{i,j=1}^{l+u} W_{w,ij} (f(x_i) - f(x_j))^2 + \frac{1}{2} \sum_{i,j=1}^{l+u} W_{b,ij} (f(x_i) - f(x_j))^2 $$

$$ + \frac{\gamma_l}{2} \sum_{i,j=1}^{l+u} W_{w,ij} (f(x_i) - f(x_j))^2 + \frac{\gamma_b}{2} \sum_{i,j=1}^{l+u} W_{b,ij} (f(x_i) - f(x_j))^2 $$

(6)

The last two terms in (6) can be further written as

$$ \frac{\gamma_l}{2} \sum_{i,j=1}^{l+u} W_{w,ij} (f(x_i) - f(x_j))^2 + \frac{\gamma_b}{2} \sum_{i,j=1}^{l+u} W_{b,ij} (f(x_i) - f(x_j))^2 $$

$$ = f^T (\gamma_l L_w + (1 - \gamma_l) D_l) f $$

(7)

where $L_w$ and $D_l$ are the graph Laplacian over the intra-class graph $G_w$ and the inter-class graph $G_b$, respectively.

SSDR actually aims to exploit the discrimination in the learning of MR, and is able to partly reduce the risk of misclassifying the boundary instances. However, from the definition of $G_w$ and $G_b$ in (4) and (5) respectively, SSDR exploits only the discrimination from the labeled data, while in semi-supervised learning, the labeled instances are usually quite limited. Thus in this paper, we attempt to utilize the discrimination from all available data, including both the given labeled and unlabeled instances.

3. Discrimination-aware manifold regularization (DAMR) for semi-supervised learning

3.1. Motivation

MR imposes the smoothness constraints over instances from both classes, thus may ignore the discrimination among instances in the boundary areas, and consequently misclassify those boundary instances, since they are very likely to belong to different classes though highly similar over the manifold. Fig. 1 gives an illustration over a linear manifold dataset consisting of two classes, each class containing 200 instances with only 10 labeled. From Fig. 1, concentrating on the smoothness only, MR (more specifically LapRLSC) derives a classification boundary (denoted by the dotted line) deviating from the real one (denoted by the dot–dash line), and thus misclassifies several boundary instances. To compensate for it, SSDR [16] utilizes the discrimination of the labeled instances together with the smoothness in MR. However, the labeled instances are usually scarce in semi-supervised classification, thus for each labeled instance, labeled instances in the opposite classes may not fall into its neighbor in the construction of the Laplacian graph, consequently, the discrimination from those labeled instances may have little effect on classification. As can be seen in Fig. 1, SSDR [16] derives the same classification boundary as MR. While considering the discrimination over the whole dataset together with the smoothness in MR, our proposed DAMR (more specifically DA_LapRLSC, detailed later) derives a classification boundary (denoted by the solid line) closer to the real one. Correspondingly, the classification accuracies for the unlabeled instances by MR, SSDR [16] and DAMR are 0.8974, 0.8974 and 0.9132, respectively. As a result, it is reasonable to consider the discrimination of all available instances in the learning of MR, which is exactly the motivation of our DAMR.

3.2. DAMR framework

In order to exploit the discrimination of all available data, we first perform some unsupervised clustering method, such as FCM, to discover the intrinsic cluster structure of the data distribution. Suppose we get a cluster indicator vector for instances from the unsupervised clustering method denoted by $Y_c = [y_{1}^{1}, ..., y_{l+u}^{1}] \in \mathbb{R}^{(l+u)}$, where each $y_{j}^{1} \in \{-1, 1\}$ represents the cluster label for the $j$th instance, then we define a discriminative matrix by $S_c = Y_c Y_{c}^{T} \in \mathbb{R}^{(l+u) \times (l+u)}$, where each $S_{ij} = y_{j} y_{i} \in \{-1, 1\}$. $S_{ij} = 1$ indicates that instances $x_i$ and $x_j$ belong to the same cluster, and $S_{ij} = -1$ indicates that $x_i$ and $x_j$ belong to different clusters. For the labeled instances, we keep the discrimination from the given labels, and define a discriminative matrix $S_l = Y_l Y_{l}^{T} \in \mathbb{R}^{(l+u) \times (l+u)}$, in which each

$$ S_{ij} = \begin{cases} 1, & \text{if both } x_i \text{ and } x_j \text{ are labeled, and belong to the same class} \\ -1, & \text{if both } x_i \text{ and } x_j \text{ are labeled, and belong to different classes} \\ 0, & \text{otherwise (either or both of } x_i \text{ and } x_j \text{ are unlabeled)} \end{cases} $$

(8)

Finally, a discriminative matrix $S_{0}$ combing the given label information and discrimination from the unsupervised clustering
method can be defined by

\[
S^0_{ij} = \begin{cases} 
S^1_{ij}, \text{ if } x_i \text{ and } x_j \text{ are both labeled} \\
S^0_{ij}, \text{ otherwise}
\end{cases}
\]

where each \( S^0_{ij} \in (-1, 1) \).

Furthermore, we introduce a weight vector for instances denoted by \( w = [w_1, \ldots, w_{n+1}]^T \), where \( w_i = 1 \) for the labeled instance and \( w_i = \gamma (0 \leq \gamma \leq 1) \) for the unlabeled instance, and set \( T = w w^T \), then we renew the discriminative matrix by

\[
S^y_{ij} = \begin{cases} 
1, \text{ if } S^0_{ij} = 1 \text{, or } T_{ij} \leq 0.5 \\
-1, \text{ otherwise (if } S^0_{ij} = -1 \text{, and } T_{ij} > 0.5) 
\end{cases}
\]

From (10), there are two cases in which the \( S^y_{ij} \) is set to 1, i.e., (1) if instances \( x_i \) and \( x_j \) belong to the same class by the class label, or the same cluster by the clustering results. (2) The confidence relating to the unlabeled instance is low, or the clustering result is unreliable such that \( T_{ij} \leq 0.5 \). In those two specific cases, we set \( S^y_{ij} \) to 1 such that the discriminative (smoothness) constraints in DAMR mainly degenerates to the smoothness constraints in MR. Otherwise, if \( x_i \) and \( x_j \) belong to different classes or clusters, and at the same time, the clustering result is reliable such that \( T_{ij} > 0.5 \), most of the discrimination constraints are kept in DAMR.

Further, we renew the weight matrix \( W \) over \( G \) as

\[
W^y_{ij} = \begin{cases} 
W^0_{ij}, \text{ if } S^y_{ij} = 1 \\
T_{ij} W^0_{ij}, \text{ otherwise}
\end{cases}
\]

where \( W^0_{ij} \) represents the similarity between instances \( x_i \) and \( x_j \) over the manifold by some distance metric. Note that the weight matrix \( W \) here differs from that in MR in that the component \( W_{ij} \) are weighted by \( T_{ij} \) when \( x_i \) and \( x_j \) belong to different classes or clusters.

In order to incorporate such discrimination, we assume that “with high similarity over the manifold, instances in the same cluster should share the same class label, and have different class labels, otherwise”, then we formulate the discrimination-aware manifold regularization framework as follows,

\[
\min_f \frac{1}{l} \sum_{i=1}^{l} V(x_i, y_i, f) + \gamma_A \|f\|_K^2 + \frac{\gamma_D}{2(l + u)} \sum_{i=1}^{l+u} W_{ij}(f(x_i) - S_{ij}g(x_j))^2
\]

where \( V(x_i, y_i, f) \) is some loss function. The last term can be further written as

\[
\frac{1}{2} \sum_{i,j=1}^{l+u} W_{ij}(f(x_i) - S_{ij}g(x_j))^2 = \mathbf{T}^T(D - W)Sf = \mathbf{T}^T \Delta \mathbf{f}
\]

where \( \Delta = D - W \) \( S \) is actually a new Laplacian matrix incorporated with the discrimination over all available instances. When \( S^y_{ij} = 1 \), i.e., \( x_i \) and \( x_j \) belong to the same class or cluster, then \( x_i \) and \( x_j \) are restricted to share the same class label when they are similar over the manifold structure, otherwise, when \( S^y_{ij} = -1 \), i.e., \( x_i \) and \( x_j \) belong to different classes or clusters, then \( x_i \) and \( x_j \) are restricted to belong to different classes though they are similar over the manifold structure. Note that we do not simply add the discriminative information to \( w_{ij} \), i.e., let \( w_{ij} = 0 \) when \( x_i \) and \( x_j \) belong to different classes or clusters, since it would lead to several problems such as non-convex [23]. On the other hand, the parameter \( \gamma \) actually adjusts the reliability or importance of the discrimination from the unsupervised clustering method. If such information is reliable or important, one can attach importance to it by setting a large \( \gamma \) value, otherwise, one can accordingly set a small \( \gamma \) value. When \( \gamma \) approaches 0, DAMR actually degenerates to MR concerning on the smoothness alone. Moreover, through exploiting the cluster discrimination in MR, the proposed DAMR framework utilizes both the cluster and manifold assumptions. Researchers have demonstrated that methods working on multiple data distribution assumptions can achieve better classification than those just working on a single one [14,15]. As a result, DAMR is able to be expected to perform better than MR.

As in MR, the minimizer of the optimization problem (13) can also be formulated as

\[
f^*(\mathbf{x}) = \sum_{i=1}^{l+u} \alpha_i K(x_i, x_i)\]

according to the Representation Theorem.

4. Discrimination-aware LapRLSC (DA-LapRLSC)

4.1. Algorithm

In terms of different loss functions, we can develop different algorithms for DAMR. We adopt the square loss in this section as an example, and derive an algorithm called Discrimination-aware LapRLSC (DA-LapRLSC). The optimization problem of DA-LapRLSC can be written as,

\[
\min_f \frac{1}{l} \sum_{i=1}^{l} (y_i - f(x_i))^2 + \gamma_A \|f\|_K^2 + \frac{\gamma_D}{2(l + u)} \sum_{i=1}^{l+u} W_{ij}(f(x_i) - S_{ij}g(x_j))^2
\]

As in MR, the minimizer of (14) can also be formulated as

\[
f^*(\mathbf{x}) = \sum_{i=1}^{l+u} \alpha_i K(x_i, x_i)\]

according to the Representation Theorem. Then (14) can be further written as

\[
\min_f = \frac{1}{l} (\mathbf{K}_A - \mathbf{Y})^T(\mathbf{K}_A - \mathbf{Y}) + \gamma_A \mathbf{K} \mathbf{A} + \frac{\gamma_D}{(l + u)^2} \mathbf{K}_L \mathbf{D} \mathbf{K}_L
\]

where \( \alpha = [\alpha_1, \ldots, \alpha_{l+u}]^T \) is the vector of Lagrange multipliers. \( \mathbf{K}_A = [\mathbf{X}_A, \mathbf{X}_U] \in \mathbb{R}^{l+u \times (l+u)} \) and \( \mathbf{K} = [\mathbf{X}, \mathbf{X}_U] \in \mathbb{R}^{l+u \times (l+u)} \) are the kernel matrices, where \( \mathbf{X} \) and \( \mathbf{X}_U \) denote the labeled and the whole datasets, respectively. \( \mathbf{Y} = [y_1, \ldots, y_l]^T \) is the vector of class labels for the labeled data. Zeroing the derivation of (15) w.r.t. \( \alpha \), we have

\[
\frac{\partial f}{\partial \alpha} = -\frac{1}{l} \mathbf{K}^T(\mathbf{K}_A - \mathbf{Y}) + \gamma_A \mathbf{K} \mathbf{A} + \frac{\gamma_D}{(l + u)^2} \mathbf{K}_L \mathbf{D} \mathbf{K}_L
\]

Finally, we have

\[
\alpha = \left( \mathbf{K}_L^T \mathbf{D}^{-1} \mathbf{K}_L + \gamma_A \mathbf{K} \mathbf{A} + \frac{\gamma_D}{(l + u)^2} \mathbf{K}_L \mathbf{D} \mathbf{K}_L \right)^{-1} \mathbf{K}_L^T \mathbf{Y}
\]

The concrete algorithm description of DA-LapRLSC is summarized in Table 1 below.

Note that though the square loss function is adopted here as an example, one can also adopt other loss functions to develop specific algorithms within the framework of DAMR.

4.2. Computation complexity

In LapRLSC, the construction of the weight matrix needs a computation complexity of \( O(n^3) \), where \( n \) is the size of the whole dataset, and the solution involves the inverse of the kernel matrix over the whole dataset with a computation complexity of \( O(n^3) \). As a result, the computation complexity of LapRLSC is \( O(n^3) \). In SSDRL in ref. [20], there is the inverse of the kernel matrix in both the construction of the discriminative kernel and the solution process, thus its computation complexity is also \( O(n^3) \). In SSDRL in ref. [16], the complexities of constructing the intra-class and inter-class graphs are both \( O(n^3) \), and the complexity of the solution is \( O(n^2) \) as in LapRLSC, thus the overall computation complexity is still \( O(n^3) \). In our DA-LapRLSC, the complexity of the clustering method is \( O(l \cdot ndi) \) [25], where \( c \) is the number of clusters, \( d \) is the dimension of the dataset, and \( i \) is the number of iterations in FCM. The complexity of constructing the discriminative matrix is \( O(n^2) \), and the complexity of the solution is \( O(n^3) \). As a result, the total
computation complexity of DA_LapRLSC is $O(c^2nd_i + n^3)$, or $O(4nd_i + n^3)$ with the cluster number set to the class number 2 here. Since both the data dimension $d$ and iteration number $i$ are commonly much smaller than the instance number $n$, the computation complexity of DA_LapRLSC can also be considered to be comparable to $O(n^3)$.

5. Experiments

In this section, we evaluate the performance of the developed DAMR framework (specifically, DA_LapRLSC) over 14 UCI datasets compared with Lap_RLSC, and two off-the-shelf improvements of MR considering the discrimination, i.e., SDDR in [24] and [16], respectively.

The descriptions of the 14 UCI datasets are given in Table 2. Each UCI dataset is randomly split into two halves, one for training and the other for testing, and the training set contains 10 and 100 labeled instances, respectively. The FCM method and linear kernel are adopted here, and the neighbor graph is used with the neighbor number $k$ fixed to 10, and the cluster number is set to the class number.

5.1. Performance comparison

The heat kernel weighting strategy is used in the graph construction. When 10 instances are labeled, $\gamma_1$ and $\gamma_2$ in Lap_RLSC are fixed to 1 and 1, respectively, $\gamma_3$, $\gamma_4$ and $\lambda$ in SDDR [24] are fixed to 1, 1, and 1, respectively, $\gamma_4$, $\gamma_5$ and $\gamma_6$ in SSDR [16] are fixed to 1, 1, and 0.6, respectively, and $\gamma_4$, $\gamma_5$ and $\gamma_6$ in DA_LapRLSC are fixed to 1, 1 and 1, respectively. When 100 instances are labeled, $\gamma$ in DA_LapRLSC and $\gamma_6$ in SSDR [16] are both selected by 5-cross validation from $[0, 0.2, 0.4, 0.6, 0.8, 1.0]$, and the other parameters are all selected from the range $[0.01, 0.1, 1, 10, 100]$. This training process is repeated 20 times and the average accuracy and variance are reported in Tables 3 and 4, respectively, in which the best performance over each dataset is highlighted in bold in each row.

From Tables 3 and 4, we can get several observations as follows,

- SDDR in [24] defines a new discriminative kernel for exploiting the discrimination in semi-supervised classification learning, and usually performs better than Lap_RLSC. Specifically, SDDR in [24] performs better than Lap_RLSC over 9 out of the 14 datasets when 10 instances are labeled, and outperforms Lap_RLSC over 12 datasets when 100 instances are labeled. As a result, utilizing the discrimination can help improving the performance of semi-supervised classification.
- Utilizing the discrimination of the labeled data, SDDR in [16] also performs better than Lap_RLSC in most cases, indicating again that the discrimination can boost learning. Specifically, SDDR in [16] performs better than Lap_RLSC over 8 datasets when 10 instances are labeled, and outperforms Lap_RLSC over

13 datasets when 100 instances are labeled. However, the improvement is not so distinct when the labeled data are scarce. As can be seen, the performance improvement of SSDR in [16] is much more distinct in the case of 100 labeled instances than that of 10 labeled instances. As a result, we attempt to exploit the discrimination of all available data in this paper.

- Through using the discrimination of all given data, DA_LapRLSC performs better than Lap_RLSC over 11 datasets when 10 instances are labeled, and outperforms Lap_RLSC over 13 datasets when 100 instances are labeled. Moreover, it performs the best over 8 datasets when 10 instances are labeled, and outperforms the other methods over 7 datasets when 100

![Graphs showing performance curves](image)

**Fig. 2.** The performances of DA_LapRLSC w.r.t. different values of $\gamma_A$ ($\gamma_D$) from {0.001, 0.01, 0.1, 1, 10, 100, 1000} over (a) automobile (b) austra (c) biomed (d) heart (e) ionosphere and (f) sonar, accuracy-$\gamma_A$ indicates the performance curve w.r.t. different values of $\gamma_A$, and accuracy-$\gamma_D$ is the performance curve w.r.t. different values of $\gamma_D$. 
instances are labeled, indicating the effectiveness of the proposed DA_LapRLSC compared with the other methods.

5.2. Parameter analysis

We show the performance of DA_LapRLSC w.r.t different values of $\gamma_A$ and $\gamma_D$, respectively, from {0.001, 0.01, 0.1, 1, 10, 100, 1000} over 6 datasets with 10 labeled instances in Fig. 2, with $\gamma$ fixed to 1. Moreover, we also give the performance of DA_LapRLSC w.r.t different values of $\gamma$ from {0, 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9, 1} in Fig. 3, with $\gamma_A$ and $\gamma_D$ both fixed to 1.

In Fig. 2, the performance of DA_LapRLSC (accuracy-$\gamma_A$) tends to increase and then decrease with the increase of $\gamma_A$. Since when $\gamma_A$ is small, DA_LapRLSC considers little about the smoothness of the decision function in the RKHS space, and when $\gamma_A$ is large, the classification of DA_LapRLSC will be dominated by such smoothness.

At the same time, the performance of DA_LapRLSC (accuracy-$\gamma_D$) in Fig. 2 tends to increase and then decrease with the increase of $\gamma_D$ over most datasets. The reason is that when $\gamma_D$ is small, DA_LapRLSC considers little about the discriminative smoothness constraints over the whole dataset, and when $\gamma_D$ is large, the classification of DA_LapRLSC will be dominated by those constraints. However, it is not the case over automobile. Specifically, the performance of DA_LapRLSC tends to decrease with the increase of $\gamma_D$ over automobile, indicating that the discrimination smoothness constraints may not be helpful for learning in this case.

Further, when $\gamma$ is small, the instance pairs satisfying $T_{ij} > 0.5$ are scarce, and the discriminative smoothness constraints in DA_LapRLSC mainly degenerate to the smoothness constraints in MR, otherwise, most of the discriminative smoothness constraints are kept in DA_LapRLSC. From Fig. 3, we can see that the performance of DA_LapRLSC tends to descend with the increase of $\gamma$ with more discriminative smoothness constraints over automobile, indicating that the discrimination smoothness constraints may not be helpful for learning here. At the same time, the performance tends to ascend with the increase of $\gamma$ over the other 5 datasets, indicating that the discrimination smoothness constraints are indeed helpful for learning in those cases.

5.3. Time complexity

We show the computation time of the compared methods with 10 instance labels in Table 5 below. From Table 5, we can see that though our DA_LapRLSC is not so competitive in efficiency, its computation time is still acceptable trading for better classification performances.

6. Conclusion

Considering that MR imposes the smoothness constraint over each instance pairs, including the instances in the boundary area, thus may misclassify those boundary instances, we develop a discrimination-aware MR (DAMR) framework in this paper through incorporating the discrimination of all available data from some unsupervised learning method. In the learning of DAMR, with high similarity over the manifold structure, instances in the same cluster are restricted to share the same class output, while instances in different clusters are restricted to have different class outputs. In this way, DAMR actually utilizes both the manifold and cluster assumptions. In the implementation, we simply use the square loss function and FCM to develop a specific DA_LapRLSC algorithm as an example. Empirical results show the competitive results of DA_LapRLSC compared with Lap_RLSC, as well as SSDR in [24] and [16], respectively.

Though we adopt the FCM method in the experiment as an example, other unsupervised learning methods or even some semi-supervised clustering method can also be adopted for exploiting the data structure with both labeled and unlabeled data, moreover, the clustering method cannot avoid grouping instances in different classes into the same cluster, thus some other strategy is also worth

---

**Fig. 3.** The performances of DA_LapRLSC w.r.t. different values of $\gamma$ from {0, 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9, 1} over (a) automobile, (b) austra, (c) biomed, (d) heart, (e) ionosphere and (f) sonar.
