Abstract—In multi-label learning, each training example is represented by a single instance while associated with multiple labels, and the task is to predict a set of relevant labels for the unseen instance. Existing approaches learn from multi-label data by assuming equal labeling-importance, i.e. all the associated labels are regarded to be relevant while their relative importance for the training example are not differentiated. Nonetheless, this assumption fails to reflect the fact that the importance degree of each associated label is generally different, though the importance information is not explicitly accessible from the training examples. In this paper, we show that effective multi-label learning can be achieved by leveraging the implicit relative labeling-importance (RLI) information. Specifically, RLI degrees are formalized as multinomial distribution over the label space, which are estimated by adapting an iterative label propagation procedure. After that, the multi-label prediction model is learned by fitting the estimated multinomial distribution as regularized with popular multi-label empirical loss. Comprehensive experiments clearly validate the usefulness of leveraging implicit RLI information to learn from multi-label data.

Keywords—multi-label learning; relative labeling-importance; label distribution

I. INTRODUCTION

Multi-label learning deals with training examples each represented by a single instance while associated with multiple labels, and the task is to learn a multi-label predictor which maps from unseen instance to relevant label set [14], [22], [30]. During the past decade, multi-label learning techniques have been widely employed to learn from data with rich semantics, such as text [21], image [3], audio [16], video [25], etc.

Formally speaking, let $\mathcal{X} = \mathbb{R}^d$ be the $d$-dimensional feature space and $\mathcal{Y} = \{y_1, y_2, \ldots, y_q\}$ be the label space with $q$ possible class labels. Given a multi-label training set $\mathcal{D} = \{(x_i, Y_i) \mid 1 \leq i \leq m\}$, where $x_i \in \mathcal{X}$ is the $d$-dimensional instance and $Y_i \subseteq \mathcal{Y}$ is the set of labels associated with $x_i$, the task is to learn a multi-label predictor $h : \mathcal{X} \rightarrow 2^\mathcal{Y}$ from $\mathcal{D}$ which maps from the space of feature vectors to the space of label sets. To learn from multi-label data, existing approaches take the common assumption of equal labeling-importance, i.e. each label associated with the training example is regarded to be relevant while the relative importance among them are not differentiated [30].

However, for real-world multi-label learning problems the importance degree of each associated label is generally different, though the importance information is not explicitly accessible from the training examples. As shown in Fig. 1, a natural scene image may be annotated with labels $sky$, $water$, $building$ and $cloud$ simultaneously, while their relative importance for characterizing this image are not explicitly provided by the annotator. Similar situations also hold for other types of multi-label data, e.g. the multiple categories associated with a news document would have different topical importance, the multiple functionalities associated with a gene would have different expression levels, etc.

Based on the above observations, we naturally postulate that effective multi-label learning can be achieved by leveraging the implicit relative labeling-importance (RLI) information. Accordingly, a novel multi-label learning approach named RELIAB, i.e. RELative Labeling-Importance Aware multi-label learning, is proposed in this paper. Firstly, the RLI degrees are formalized as multinomial distribution over the label space, which are estimated by invoking an iterative label propagation procedure over the training examples.

Figure 1. An exemplar natural scene image which has been annotated with multiple labels $sky$, $water$, $building$ and $cloud$. The relative importance of each label is illustrated in the figure, which has not been explicitly provided by the annotator. In addition, the label $pedestrian$ is not annotated for the image due to its insignificant appearance.
After that, a multi-label predictor is induced by fitting the prediction model with the estimated multinomial distribution along with multi-label empirical loss regularization. Extensive experiments across 17 benchmark multi-label data sets show that RELIAB performs favorably against state-of-the-art multi-label learning approaches.

The rest of this paper is organized as follows. Section II presents technical details of the proposed approach. Section III discusses existing works related to RELIAB. Section IV reports experimental results of comparative studies. Finally, Section V concludes.

II. THE RELIAB APPROACH

As shown in Section I, the task of multi-label learning is to induce a multi-label predictor \( h : \mathcal{X} \to 2^\mathcal{Y} \) from the training set \( D = \{ (x_i, Y_i) \mid 1 \leq i \leq m \} \). Given any instance \( x = [x_{i1}, x_{i2}, \ldots, x_{id}]^\top \in \mathcal{X} \) and label \( y_i \in \mathcal{Y} \), we use \( \mu_{x}^{y} \) to denote the implicit RLI degree of \( y_i \) for characterizing \( x \).

Intuitively speaking, the higher the value of \( \mu_{x}^{y} \), the more semantics conveyed by \( y_i \) in characterizing \( x \).

Accordingly, the set of relevant labels \( Y \) for \( x \) can be determined as: \( Y = \{ y_i \mid \mu_{x}^{y} > t(x), 1 \leq l \leq q \} \), where \( t(x) \) corresponds to the threshold value which separates relevant labels from irrelevant ones for instance \( x \). In this paper, we enlarge the original label space \( \mathcal{Y} \) for \( X \) into \( \hat{\mathcal{Y}} = \{ y_0 \} \bigcup \mathcal{Y} \), where \( y_0 \) is the complementary virtual label serving as an artificial bipartition point between relevant and irrelevant labels [8], [17], [22], [30]. In this case, \( t(x) \) can be viewed as the thresholding-importance w.r.t. virtual label \( y_0 \), i.e. \( \mu_{x}^{y_0} \).

We therefore have the following definition on RLI degree as follows:

**Definition. Relative Labeling-Importance (RLI) Degree**

Given any instance \( x \in \mathcal{X} \), the RLI degree of label \( y_i \in \hat{\mathcal{Y}} \) for \( x \) is denoted as \( \mu_{x}^{y} \) (\( 0 \leq i \leq q \)), which satisfies the following constraints:

(i) non-negativity: \( \mu_{x}^{y} \geq 0 \)

(ii) normalization: \( \sum_{y} \mu_{x}^{y} = 1 \)

Furthermore, the set of relevant labels \( Y \subseteq \hat{\mathcal{Y}} \) for \( x \) can be determined as: \( Y = \{ y_i \mid \mu_{x}^{y} > \mu_{x}^{y_0}, 1 \leq l \leq q \} \).

There are three points which need to be noticed for the RLI degree formulated as above. Firstly, the RLI degree is not directly accessible from the multi-label training examples and thus implicit to the learning algorithm. Secondly, the RLI degree is instance-dependant which corresponds to the relative importance among all labels in characterizing the semantics of one particular instance. Thirdly, the RLI degree for each instance, i.e. \( \mu_{x}^{y} \), can be viewed as a label distribution over the label space \( \hat{\mathcal{Y}} \). For label distribution learning (LDL) [10], [11], [12], the distribution information is assumed to be available while for multi-label learning the RLI information needs to be further inferred.

In this paper, RELIAB learns from multi-label data in two basic stages, i.e. implicit RLI degree estimation and prediction model induction, which are scrutinized in the following subsections respectively.

A. Implicit RLI Degree Estimation

In the first stage, RELIAB aims to estimate the implicit RLI degree for all training examples, i.e. \( U = \{ \mu_{x}^{y} \mid 1 \leq i \leq m, 0 \leq l \leq q \} \). To fulfill this task, the widely-used iterative label propagation techniques [31], [33] is adapted for the estimation. Let \( G = (V, E) \) denote the fully-connected graph constructed over the set of training examples with \( V = \{ x_i \mid 1 \leq i \leq m \} \). Furthermore, an \( m \times m \) symmetric similarity matrix \( W = [w_{ij}]_{m \times m} \) is specified for \( G \) as follows:

\[
\forall_{i,j=1}^{m}: w_{ij} = \begin{cases} 
\exp\left(-\frac{\| x_i - x_j \|^2_2 }{\sigma^2} \right), & \text{if } i \neq j \\
0, & \text{if } i = j 
\end{cases}
\]  

(1)

Here, \( \sigma > 0 \) is the width parameter for similarity calculation, which is fixed to be 1 in this paper.

Correspondingly, a label propagation matrix \( P \) is constructed from the similarity matrix: \( P = D^{-\frac{1}{2}} WD^{-\frac{1}{2}} \).

Here, \( D = \text{diag}[d_1, d_2, \ldots, d_m] \) is a diagonal matrix with its diagonal entry \( d_i \) equal to the sum of the \( i \)-th row of \( W: d_i = \sum_{j=1}^{m} w_{ij} \). Let \( F = [f_{it}]_{m \times (q+1)} \) be an \( m \times (q+1) \) matrix with non-negative entries, where \( f_{it} \geq 0 \) is assumed to be proportional to the labeling-importance \( \mu_{x}^{y_i} \). Based on the multi-label training set, an initial matrix \( F^{(0)} = \Phi = [\phi_{it}]_{m \times (q+1)} \) is instantiated as follows:

\[
\forall_{i=1}^{m} \forall_{q=1}^{q}: \phi_{it} = \begin{cases} 
\tau, & \text{if } y_i = y_0 \\
1, & \text{if } y_i \in Y_i \\
0, & \text{otherwise}
\end{cases}
\]  

(2)

Here, \( \tau \in (0, 1) \) is the initial thresholding-importance parameter for virtual label \( y_0 \). As shown in Eq.(2), at the initialization step, all the relevant (irrelevant) labels are assumed to have unit (zero) labeling-importance. At the \( t \)-th iteration, \( F \) is updated by propagating labeling-importance information with the label propagation matrix \( P \):

\[
F^{(t)} = \alpha P F^{(t-1)} + (1 - \alpha) \Phi
\]  

(3)

Here, \( \alpha \in (0, 1) \) is the balancing parameter which controls the fraction of information inherited from label propagation (i.e. \( P F^{(t-1)} \)) and initial labeling (i.e. \( \Phi \)).

By applying Eq.(3) recursively with \( F^{(0)} = \Phi \), it is not difficult to show that:

\[
F^{(t)} = (\alpha P)^t \Phi + (1 - \alpha) \sum_{i=0}^{t-1} (\alpha P)^i \Phi
\]  

(4)
As a real symmetric matrix, the label propagation matrix \( P \) can be diagonalized as \( P = C^T \Lambda C \), where \( C \) is an orthonormal matrix and \( \Lambda = \text{diag} [\lambda_1, \lambda_2, \ldots, \lambda_m] \) is a diagonal matrix containing eigenvalues of \( P \). Note that \( P \) is similar to \( S = D_{1/2} P D_{1/2} = D^{-1} W \), and therefore \( P \) and \( S \) share identical eigenvalues.

Since \( S \) is a stochastic matrix whose rows consist of non-negative entries and sum to one, the absolute value of each eigenvalue satisfies \( |\lambda_i| \leq 1 \) (1 \( \leq i \leq q \)) as ensured by the Perron-Frobenius theorem [18], [33]. Under the setting of \( \alpha \in (0, 1) \), the limit for the first term of Eq.(4) would be:

\[
\lim_{t \to \infty} (\alpha P)^t \Phi = \lim_{t \to \infty} \alpha^t \cdot (C^T \Lambda C)^t \Phi
= \lim_{t \to \infty} \alpha^t \cdot C^T \Lambda^t C \Phi
= 0
\]

(5)

It also holds that \( \lim_{t \to \infty} \sum_{i=0}^{t-1}(\alpha P)^i = (I - \alpha P)^{-1} \) because:

\[
(I - \alpha P) \lim_{t \to \infty} \sum_{i=0}^{t-1}(\alpha P)^i = \lim_{t \to \infty} (I - \alpha P) \sum_{i=0}^{t-1}(\alpha P)^i
= \lim_{t \to \infty} (I - (\alpha P)^t)
= I
\]

Thus, the limit for the second term of Eq.(4) would be:

\[
\lim_{t \to \infty} (1 - \alpha) \sum_{i=0}^{t-1}(\alpha P)^i \Phi = (1 - \alpha)(I - \alpha P)^{-1} \Phi
\]

(6)

According to Eqs.(5) and (6), \( F^t \) will converge to \( F^* \) as the number of iterations grow:

\[
F^* = (1 - \alpha)(I - \alpha P)^{-1} \Phi
\]

(7)

Based on \( F^* \), the implicit RLI degree for each training example is estimated as:

\[
\forall_{i=1}^{m} \forall_{q=0}^{q} \mu_{x_i}^{y_i} = \frac{f_{x_i}^*}{\sum_{k=0}^{q} f_{x_k}^*}
\]

(8)

In other words, the set of \( q+1 \) RLI degrees for each instance \( x_i \), i.e. \( \{\mu_{x_i}^{y_i} | 0 \leq l \leq q\} \), can be regarded as a multinomial distribution over the (enlarged) label space \( \tilde{Y} \), which are obtained by normalizing \( F^* \) on each row.

### B. Prediction Model Induction

In the second stage, RELIAB aims to induce the multi-label prediction model by leveraging the implicit RLI information estimated in the first stage, i.e. \( U = \{\mu_{x_i}^{y_i} | 1 \leq i \leq m, 0 \leq l \leq q\} \). To facilitate the exploitation of \( U \), we employ the simple maximum entropy model [5], [12] to parametrize the multi-label predictor:

\[
\forall_{i=0}^{q} \quad f(y_l | x, \Theta) = \frac{1}{Z(x)} \exp (\theta_l^T x)
\]

(9)

Here, \( \Theta = [\theta_0, \theta_1, \ldots, \theta_q] \) represents the set of model parameters and \( \theta_l = [\theta_{1l}, \theta_{2l}, \ldots, \theta_{dl}]^T \) is the \( d \)-dimensional weighting parameter vector for the \( l \)-th label \( y_l \in \tilde{Y} \). Furthermore, the partition function \( Z(x) = \sum_{l=0}^{q} \exp(\theta_l^T x) \) serves as a normalization term to ensure distributional outputs over \( \tilde{Y} \):

\[
\sum_{l=0}^{q} f(y_l | x, \Theta) = 1
\]

In this case, the multi-label predictor \( h \) can be derived from \( f \) by thresholding the outputs against the virtual label \( y_0 \):

\[
h(x) = \{ y_l | f(y_l | x, \Theta) > f(y_0 | x, \Theta), 1 \leq l \leq q \}
\]

(10)

To induce the parametric model \( f \), RELIAB chooses to optimize the following objective function:

\[
V(f, U, D) = V_{dis}(f, U) + \beta \cdot V_{emp}(f, D)
\]

(11)

The first term \( V_{dis}(f, U) \) considers how the parametric model \( f \) fits the estimated RLI degrees \( U \), while the second term \( V_{emp}(f, D) \) is used as a regularizer which considers how \( f \) classifies the multi-label training examples in \( D \).

On one hand, \( V_{dis}(f, U) \) can be measured by the compatibility between the importance-based distribution, i.e. \( \{\mu_{x_i}^{y_i} | 0 \leq l \leq q\} \), and the model-based distribution, i.e. \( \{f(y_l | x, \Theta) | 0 \leq l \leq q\} \). Here, the canonical Kullback-Leibler (KL) divergence is employed to instantiate the first term of Eq.(11):

\[
V_{dis}(f, U) = \sum_{i=1}^{m} \sum_{l=0}^{q} \left( \mu_{x_i}^{y_l} \ln \frac{\mu_{x_i}^{y_l}}{f(y_l | x_i, \Theta)} \right)
\]

(12)

On the other hand, \( V_{emp}(f, D) \) can be measured by the empirical loss of the parametric model \( f \) on \( D \). As shown in Eq.(10), by taking the virtual label \( y_0 \) as the bipartition point, its modeling output \( f(y_0 | x_i, \Theta) \) should be less than those of relevant labels in \( Y_i \) while larger than those of irrelevant labels in \( \tilde{Y} \setminus Y_i \). Accordingly, the second term of Eq.(11) is instantiated as:

\[
V_{emp}(f, D) = -\sum_{i=1}^{m} \left( \sum_{j=0}^{q} f(y_j | x_i, \Theta) - f(y_0 | x_i, \Theta) \right)
+ r_i \cdot \sum_{j=0}^{q} \left( f(y_j | x_i, \Theta) - f(y_k | x_i, \Theta) \right)
\]

(13)

Here, \( r_i = |Y_i|/|\tilde{Y}_i| \) is used to account for potential imbalance between the number of relevant and irrelevant labels associated with each example [28]. Note that minimizing the loss in Eq.(13) can be viewed as minimizing one of the most popular multi-label metrics, namely the ranking loss [2], [9], [22], [30], which considers pairwise ranking between each relevant-irrelevant label pair. Nonetheless, by incorporating the virtual label \( y_0 \), the number of pairwise relationships.
to be considered can be reduced from $O(q^2)$ for traditional ranking loss to $O(q)$ for the loss in Eq.(13).

By substituting Eqs.(12) and (13) into the objective function and ignoring constant terms, Eq.(11) can then be rewritten as:

$$V(f,\mathcal{U},\mathcal{D}) = -\sum_{i=1}^{m} \sum_{l=0}^{q} \left( \mu_{x_i}^{y_l} \ln f(y_l | x_i, \Theta) \right)$$

$$-\beta \cdot \sum_{i=1}^{m} \left( \sum_{y_j \in \mathcal{Y}_i} \left( f(y_j | x_i, \Theta) - f(y_0 | x_i, \Theta) \right) \right)$$

$$+ r_i \cdot \sum_{y_k \in \mathcal{Y}_i} \left( f(y_0 | x_i, \Theta) - f(y_k | x_i, \Theta) \right)$$

(14)

The final prediction model $f^*$ is obtained by minimizing Eq.(14), i.e. $f^* = \arg\min_{f} V(f,\mathcal{U},\mathcal{D})$. To solve the corresponding unconstrained nonlinear optimization problem, RELIAB employs the Limited-memory Broyde-Fletcher-Goldfarb-Shanno (L-BFGS) algorithm which is particularly suited for problems with large number of variables [19]. As a quasi-Newton algorithm, L-BFGS iteratively optimizes the objective function with respect to gradient of the function:

$$\frac{\partial V}{\partial \Theta} = \left[ \frac{\partial V}{\partial \theta_0}, \frac{\partial V}{\partial \theta_1}, \cdots, \frac{\partial V}{\partial \theta_q} \right]$$

where

$$\frac{\partial V}{\partial \theta_l} = -\sum_{i=1}^{m} \left( \left( \mu_{x_i}^{y_l} - f(y_l | x_i, \Theta) \right) \cdot x_i \right) - \beta \cdot \sum_{i=1}^{m} \left( f(y_l | x_i, \Theta) - f(y_j | x_i, \Theta) \right)$$

$$+ r_i \cdot \sum_{y_k \in \mathcal{Y}_i \setminus \{y_l\}} \left( f(y_k | x_i, \Theta) - f(y_0 | x_i, \Theta) \right)$$

$$+ \zeta(y_l, Y_i) \left( 1 - f(y_l | x_i, \Theta) + f(y_0 | x_i, \Theta) \right) \cdot x_i$$

(15)

Here, $\zeta(y_l, Y_i)$ returns 0 if $y_l$ corresponds to the virtual label $y_0$. Otherwise, $\zeta(y_l, Y_i)$ returns +1 if $y_l \in Y_i$ and $-r_i$ if $y_l \in \bar{Y}_i$.

Table I summarizes the complete procedure of the proposed RELIAB approach. After incorporating the virtual label $y_0$ into the original label space (Step 1), a similarity matrix as well as an initial labeling-importance matrix are constructed based on the training examples (Steps 2-3). After that, the implicit degrees of RLI are estimated via a label propagation procedure (Steps 4-5), and then the multi-label prediction model is learned by leveraging the estimated labeling-importance information (Steps 6-14). Finally, the predicted model set for unseen instance is determined by thresholding the model outputs against the virtual label (Step 15).²

²Code package for RELIAB is publicly available at http://cse.seu.edu.cn/PersonalPage/zhangml/files/RELIAB.zip

### III. RELATED WORK

Existing works related to RELIAB are briefly discussed in this section, while more comprehensive reviews on multilabel learning can be found in [14], [22], [30].

Existing approaches to multi-label learning can be roughly grouped into three categories based on the order of label correlations being considered [22], [30], i.e. first-order approaches assuming independence among class labels [1], [29], second-order approaches considering correlations between a pair of class labels [7], [8], and high-order approaches considering correlations among label subsets or all the class labels [15], [20], [23]. For whichever order of correlations, the common modeling strategy is to treat each label in a crisp manner, i.e. being either relevant or irrelevant for an instance without differentiating its relative importance. In contrast, RELIAB models high-order label correlations by differentiating degrees of RLI over the label

order of $|S|$, with nine of them being regular-scale (first part, $|S| < 5,000$) and eight of them being large-scale (second part, $|S| \geq 5,000$). As shown in Table III, the seventeen data sets cover a broad range of cases with diversified multi-label properties and thus serve as a solid basis for thorough comparative studies.

2) Comparing Algorithms: In this paper, we choose to compare the performance of REILAB against four well-established multi-label learning algorithms \cite{30}, including first-order approach binary relevance (BR) \cite{23}, second-order approach calibrated label ranking (CLR) \cite{8}, and high-order approaches ensemble of classifier chains (ECC) \cite{20} and random k-labelsets (RAKEL) \cite{23}.

As shown in Eq.(9), the parametric predictor employed by REILAB can be viewed equivalently as multinomial logistic regression models. Accordingly, each of the four comparing algorithms are implemented under the MULAN multi-label learning package \cite{24} by instantiating their base learners with logistic regression models. Furthermore, parameters suggested in the literatures are used for ECC and RAKEL (ECC: ensemble size 30; RAKEL: ensemble size $2q$ with $k = 3$). For REILAB, the balancing parameter $\alpha$ is fixed to be 0.5 which yields stable performance across the experimental data sets. In addition, the initial threshold-importance parameter $\tau$ and the regularization parameter $\beta$ are chosen among \{0.1, 0.15, . . . , 0.5\} and \{10^{-3}, 10^{-2}, . . . , 10\} respectively by conducting cross-validation on training set.

3) Evaluation Protocol: A number of evaluation metrics specific to multi-label learning have been proposed, which can be generally categorized into two groups \cite{22}, \cite{30}, i.e. example-based metrics and label-based metrics. Example-based metrics work by evaluating the predictor’s performance on each test example separately and then returning the mean value across all test examples. On the other hand, label-based metrics work by evaluating the predictor’s performance on each label separately and then returning the macro/micro-averaged value across all class labels.

In this paper, six widely-used multi-label metrics are employed for performance evaluation, including four example-based metrics: one-error, coverage, ranking loss, average precision, and two label-based metrics: macro-averaging F1, micro-averaging F1. These evaluation metrics consider the performance of multi-label predictor from various aspects, whose values all vary between [0,1]. For one-error, coverage and ranking loss, the smaller the value the better the performance. For the other three metrics, the larger the values the better the performance.

For each comparing algorithm, ten-fold cross-validation is performed on regular-scale data sets (first part of Table III) while five-fold cross-validation is performed on large-scale data sets (second part of Table III). Accordingly, the mean metric value as well as the standard deviation are recorded for comparative studies.

C. Experimental Results

Tables IV and V report the detailed experimental results of all comparing algorithms on the regular-scale and large-scale data sets respectively. For each evaluation metric, “↓” indicates “the smaller the better” while “↑” indicates “the larger the better”. Furthermore, the best performance among the five comparing algorithms is shown in boldface.

To analyze the relative performance among the comparing algorithms systematically, Friedman test \cite{6} is used here which is regarded as the favorable statistical test for comparisons among multiple algorithms over a number of data sets. Table VI summarizes the Friedman statistics $F_F$.
and the corresponding critical values on each evaluation metric. As shown in Table VI, at 0.05 significance level, the null hypothesis of indistinguishable performance among the comparing algorithms is clearly rejected on each evaluation metric. Consequently, Bonferroni-Dunn test [6] is employed as the post-hoc test to show the relative performance among the comparing algorithms, where RELIAB is treated as the control algorithm. Here, the average rank difference between RELIAB and one comparing algorithm is calibrated with the critical difference (CD). Accordingly, the performance between RELIAB and one comparing algorithm is deemed to be significantly different if their average ranks differ by at least one CD (CD=1.3547 in this paper: # comparing algorithms k = 5, # data sets N = 17).

Fig. 2 illustrates the CD diagrams [6] on each evaluation metric, where the average rank of each comparing algorithm is marked along the axis (lower ranks to the right). In each subfigure, any comparing algorithm whose average rank is within one CD to that of RELIAB is interconnected to each other with a thick line. Otherwise, it is considered to have significantly different performance against RELIAB.

Based on the above experimental results, the following observations can be apparently made:

1) On regular-scale data sets (Table IV), across all the evaluation metrics, RELIAB ranks 1st in 83.3% cases and ranks 2nd in 11.1% cases; On large-scale data sets...

(Related values across all the evaluation metrics, RELIAB ranks 1st in 68.7% cases and ranks 2nd in 16.7% cases.

2) RELIAB achieves optimal (lowest) average rank in terms of each evaluation metric (Fig. 2(a)-(f)). Furthermore, RELIAB significantly outperforms Br on all the evaluation metrics.

3) RELIAB is comparable to RAKEL in terms of macro-averaging F1 (Fig. 2(e)), comparable to CLR in terms of coverage (Fig. 2(b)) and ranking loss (Fig. 2(c)), and significantly outperforms RAKEL and CLR on all the other cases. The comparable performance between RELIAB and CLR on ranking loss is also noticeable, as CLR is designed to learn from multi-label data by optimizing this particular evaluation metric [8, 30].

4) RELIAB is comparable to ECC in terms of example-based evaluation metrics (Fig. 2(a)-(d)), and significantly outperforms ECC in terms of label-based evaluation metrics (Fig. 2(e)-(f)). It is worth noting that ensemble learning techniques has been utilized by ECC to improve generalization, and the number of base learners employed by ECC is M-times larger than those employed by RELIAB (as specified in Subsection IV-B2, ensemble size M for ECC is set to be 30 in this paper).

To summarize, RELIAB achieves rather competitive performance against the well-established multi-label learning algorithms across extensive benchmark data sets and diverse evaluation metrics, which validate the effectiveness of leveraging implicit RLI information to learn from multi-label data.

D. Further Analysis

In this subsection, one variant of RELIAB is implemented to further analyze certain properties of the proposed approach. As shown in Subsection II-B, the parametric model is learned by fitting the estimated labeling-importance as regularized with multi-label empirical loss. To show the
helpfulness of regularization, another variant of RELIAB is designed by dropping the regularization term $V_{\text{emp}}(f, D)$ (Eq.(11)) from the objective function of RELIAB. Thereafter, the resulting variant is denoted as RELIAB-nonREG.

Accordingly, the performance of RELIAB-nonREG is evaluated following the same protocol of Subsection IV-B3. Due to space limit, detailed experimental results of the variant are not reported here. Nonetheless, to show whether RELIAB performs significantly better than its variant, the Wilcoxon signed-ranks test [6], [26] is used here which is a desirable statistical test for comparisons between two algorithms over a number of data sets. Table VII summarizes the statistical test results at 0.05 significance level, where the $p$-values for the corresponding tests are also shown in the brackets.

As shown in Table VII, RELIAB achieves comparable performance against RELIAB-nREG on Coverage, Macro-averaging F1 and Micro-averaging F1, while significantly outperforms RELIAB-nREG on all the other evaluation metrics. These results indicate that the regularization term based on multi-label empirical loss does help induce robust parametric models. Actually, the implicit RLI information exploited in the first objective term $V_{\text{dis}}(f, U)$ (Eq.(11)) are only estimations instead of being ground-truth values. In this case, optimizing objective function without necessary regularization is prone to produce unstable prediction models.

In this paper, the problem of multi-label learning is addressed by taking into account the fact that the relative labeling-importance is different for each label associated with the multi-label data. Accordingly, a novel multi-label learning approach named RELIAB is proposed, which works by leveraging the implicit RLI information derived from the training examples for model induction. Extensive comparative studies clearly validate the superiority of RELIAB against state-of-the-art multi-label learning approaches. In the future, we will explore if there exist better ways to estimate and make use of the implicit RLI information.

### V. Conclusion

The problem of multi-label learning is addressed by taking into account the fact that the relative labeling-importance is different for each label associated with the multi-label data. Accordingly, a novel multi-label learning approach named RELIAB is proposed, which works by leveraging the implicit RLI information derived from the training examples for model induction. Extensive comparative studies clearly validate the superiority of RELIAB against state-of-the-art multi-label learning approaches. In the future, we will explore if there exist better ways to estimate and make use of the implicit RLI information.
